#### Abstract

The question of stability of slopes exhibits its frequent presence in most part of the Garhwal Himalayas in the form of creeping, rock falls and slides of varying magnitudes leading to a degree of damages to human lives and resources. It is well known that the process of hill slope instability is a multi-causal phenomena and the topographic-geologic surface intersection plays a vital role in it. The effort has been made in the present study to examine this specific factor in a particular river basin unit through field data collection and statistical analysis on it for reaching towards a rational conclusion.

Keywords: Cataclinal, anaclinal, orthoclinal, landslide, hill slope instability.

## Introduction

The phenomenon of hill slope instability is a typical process resulted from the complicated interaction of different geologic, tectonic and geomorphic factors along with a vital role of anthropogenic activities over the slopes; and this process results into a certain degree of loss of human lives and resources at different part of the world which has added another perspective of studying the process from the standpoint of 'environmental hazard'. As Smith mentioned that the term 'environmental hazard' has the advantage of including both natural and human dimensions; besides, this dual perspective also bring forth enormous scholarly debate to establish whether a particular hazard has greater influence from nature or man ${ }^{1}$.

However, there is a generalized understanding - if the degree of responsibility of individual human being is concerned, the responsibility factor increases greatly from the large scale geophysical hazards (e.g. earthquake) towards the social hazards (e.g. smoking) that are largely self-induced in nature. When the issue of slope instability is concerned, the geological and structural settings of slopes are considered as the main predisposing factors for the scientific observations and analysis of the phenomena of hill slope instability ${ }^{2-4}$. Bedding of lithological sequences with complexity of arrangements ${ }^{5,6}$, the issues of contacts - stratigraphic or tectonic, between rocks with varying geo-mechanical and severely fractured zones that are linked to the presence of axes of folds and faults etc are all favorable geological conditions towards making the hill slope instable ${ }^{7,8}$. The observations of these elements at different scales play fundamental role in understanding the slope instability mechanism. When the targeted process for observation and measurement is allied with the landslide, then it is the bedding planes of layered formations that can control both the landslide
mechanism and the activity, in terms of style, magnitude and distribution ${ }^{9}$. The analysis of the relationship between bedding plain attitude and topography may be considered as one of the key procedures to identify and comprehend how far a particular slope unit is controlled by structural parameters. This is also to be noted that the geometric relationships between topography and geologic structure influences the process of sub-surface drainage and mass wasting of a particular slope unit ${ }^{10,11}$. The present study tries to examine the influence of geologictopographic surface intersection on hill slope instability processes in a particular river basin unit.

The present study has been conducted in the basin of the river Mousi, a small southbound river. The river basin is situated at the south-eastern direction of the Mussorrie Town of Garhwal District, Uttarakhand, having a north-south stretching elongated shape. The study area is geographically extended between $78^{\circ} 05^{\prime} 00^{\prime \prime} \mathrm{E}$ - $78^{0} 07^{\prime} 30^{\prime \prime} \mathrm{E}$ longitude and $30^{\circ} 23^{\prime} 35.22^{\prime} \mathrm{N}$ $30^{0} 29^{\prime} 57^{\prime \prime} \mathrm{N}$ latitude. The basin covers a total of $17.2 \mathrm{~km} .^{2}$ of area. The basin area of river Mousi is located in Lesser Himalaya and it has a close association with the Main Boundary Thrust (MBT) which is a tectonic discontinuity, dipping northnortheast, and bringing the Lesser Himalayan rocks in juxtaposition with the rocks of Siwalicks. The northern part of the study area including the Mussoorie town comes within the zone IV of the Seismic Zonation Map of India ${ }^{12}$. Proximity to the major seismic discontinuity is responsible for fragility of the terrain that consists of highly fractured and sheared rock mass of mostly limestone, dolomitic limestone, calcareous sandy shale, micaceous sandy siltstone, grey and black shale, silty shale, quartzite and chert ${ }^{13}$. The area witnesses the incidences of hill slope instability of varying magnitude and forms, accompanied with a varying degree of structural damages.

Figure-1

## Location of the study area

The present study tries - i. to observe the litho-structuraltopographic control on hill slope forms and processes; ii. to examine the interrelationship between topographic/bedding plane intersection and hill slope instability and iii. to interpret the relationship for obtaining a concluding remark.

## Material and Methods

Assessment of Hill Slope Instability: The degree of hill slope instability cannot be measured directly as it ranges from a very Testing the significance of relationship of slope instability with different morpho-structural parameters individually:
slow process like creep to very rapid process like landslide. The close observations on slope units for identifying the signs or evidences of active or past mass movement processes leads to establish a scaling device to measure the degree of hill slope instability; and the slope units of the present study area reflect distinct evidences of three mass movement processes mainly creep, rock fall and slide. The assessment of the slope instability has been done using an weighted scoring (table-1) namely Weighted Index of Slope Instability $(0 \leq \xi \leq 10)$.

Pearson's Correlation Coefficient is used to find out the relationship between different morpho-strutural parameters and
the WISI ( $\xi$ ); and the T-test is applied to determine the significance of relationship in between the them.

Classification of Slopes using Chord Length: Slopes are classified into three categories, namely-cataclinal, anaclinal and orthoclinal, on the basis of the interrelationship between the azimuth of topographic slope (A) and the azimuth of bedding $\operatorname{dip}(\alpha)$.

Chord Length $(\mathrm{L})=\sqrt{(\cos \alpha-\cos A)^{2}+(\sin \alpha-\sin A)^{2}}$
Using the value of the magnitude of topographic slope (S) and the bedding dip $(\Theta)$, the cataclinal and anaclinal slopes can be further sub-classified ${ }^{14}$ (table-2).
Calculating the Topographic-Bedding plane Intersection
Angle (TOBIA): This Index has been used by Meentemeyer
and Moody ${ }^{14}$ through the modification of the logic used for modeling the topographic variability to solar radiation by Dozier ${ }^{15}$ and Dubayah ${ }^{16}$.

TOBIA $(\tau)=\{(\cos \theta \cdot \cos S)+(\sin \theta \cdot \sin S) \cdot \cos (\alpha-A)\}$
The value of $\tau$ can be used successfully as an index to represent the conformity between topographic and bedding surfaces and the value of this index ranges from one to negative one $(-1 \leq \tau \leq$ 1).

## Results and Discussion

The Weighted Index of Slope Instability $(0 \leq \xi \leq 10)$ has been calculated for the observations on randomly selected 43 slope units throughout the basin of river Mousi (table-3).

Table-1
Weighting and Scoring pattern for Weighted Index of Slope Instability ( $\xi$ )

| Mass movement evident | Degree of Slope Instability | Maximum score to be assigned | Intensity | Score to be assigned |
| :---: | :---: | :---: | :---: | :---: |
| Creep | Low | 1 | No creep | 0.00 |
|  |  |  | Low | 0.33 |
|  |  |  | Moderate | 0.66 |
|  |  |  | High | 1.00 |
| Rock Fall | Moderate | 2 | No rock fall | 0.00 |
|  |  |  | Slight | 0.66 |
|  |  |  | Moderate | 1.33 |
|  |  |  | Rapid | 2.00 |
| Old Landslide | High | 3 | No scar of old landslide | 0.00 |
|  |  |  | <1000 cubic m. mass displaced | 1.00 |
|  |  |  | 1000-2000 cubic m. mass displaced | 2.00 |
|  |  |  | >2000 cubic m. mass displaced | 3.00 |
| Active Landslide | Very High | 4 | No scar of active landslide | 0.00 |
|  |  |  | <1000 cubic m. mass displaced | 1.33 |
|  |  |  | 1000-2000 cubic m. mass displaced | 2.66 |
|  |  |  | >2000 cubic m. mass displaced | 4.00 |

Table-2
Classification of Slope Units (after Meentemeyer and Moody, 1994)

| Chord Length (L) | Slope Type | $(\boldsymbol{\theta}-\mathbf{S})$ | Sub-category |
| :---: | :---: | :---: | :---: |
| $0 \leq \mathrm{L} \leq 0.7654$ | Cataclinal Slope ( $\mathrm{a}_{\mathrm{c}}$ ) | $(\Theta-S)<-5^{0}$ | Overdip Slope ( $\mathrm{a}_{\mathrm{c} / \mathrm{o}}$ ) |
|  |  | $-5^{0} \leq(\Theta-S) \leq 5^{0}$ | Dip Slope ( $\mathrm{a}_{\text {c/d }}$ ) |
|  |  | $(\Theta-S)>5^{0}$ | Underdip Slope ( $\mathrm{a}_{\mathrm{c} / \mathrm{u}}$ ) |
| $0.7654<\mathrm{L} \leq 1.8478$ | Orthoclinal Slope ( $\mathrm{a}_{0}$ ) | - | - |
| $1.8478<\mathrm{L} \leq 2$ | Anaclinal Slope ( $\mathrm{a}_{\mathrm{a}}$ ) | $(\mathrm{O}-\mathrm{S})<-5^{0}$ | Steepened Escarpment ( $\mathrm{a}_{\mathrm{a} / \mathrm{t}}$ ) |
|  |  | $-5^{0} \leq(\Theta-S) \leq 5^{0}$ | Normal Escarpment ( $\mathrm{a}_{\text {a/n }}$ ) |
|  |  | $(\Theta-S)>5^{0}$ | Subdued Escarpment ( $\mathrm{a}_{\text {a }}$ ) |

For the above mentioned 43 slope units, the Magnitude of True Dip $(\Theta)$ has been calculated using the collected data of Magnitude ( $\Theta^{\prime}$ ) as well as Azimuth ( $\alpha^{\prime}$ ) of Apparent Dip; and Azimuth of True Dip ( $\alpha$ ) with the help of the following
relationship between the Apparent and True Dip of bedding strata (table-4).
$\Theta=\arctan \left(\tan \Theta^{\prime} / \cos \delta\right) ;$ where, $\delta=\left(\alpha \sim \alpha^{\prime}\right)$

Table-4
Converting apparent dip to true dip

Now, the values of observed morpho-structural parameters i.e. altitude (h), magnitude of topographic slope (S), azimuth of topographic slope (A), magnitude of bedding dip ( $\Theta$ ) and azimuth of bedding dip $(\alpha)$ are treated as independent variables and WISI ( $\xi$ ) is treated as dependent variable. Pearson's Correlation Coefficient (r) is calculated for each set (table-5 for
detailed dataset of calculation of r). T-test (at $95 \%$ confidence level) applied to each set of relationship for testing the null hypothesis that "there is no significant relationship between each individual morpho-structural parameters and WISI (i.e. h with $\xi$, S with $\xi$, A with $\xi, \theta$ with $\xi$ and $\alpha$ with $\xi) "$.

Only for the relationship between S and $\xi$, the $\mathrm{T}>\mathrm{T}_{0.975(\mathrm{df}=\mathrm{x})}$; so, in this case, the null hypothesis is rejected. For rest of the cases, $\mathrm{T}<\mathrm{T}_{0.975(\mathrm{df}=\mathrm{x})}$; hence, Null Hypothesis is accepted; therefore, these relationships are statistically insignificant (table-6).

The test of significance bring to fore the conclusion that altitude, direction of topographic slope and magnitude as well as azimuth of bedding dip, as individual factors, hardly influence the issue of hill slope instability. Only, the magnitude of topographic slope shows significant positive relationship with the degree of slope instability in the area under observation. Under this circumstance a combination of topographic and bedding parameters are required to be correlated with the WISI to interpret the morpho-structural influence on hill slope instability.

The Topographic-Bedding Plane Intersection Angle (TOBIA) has been calculated for each of 43 slope units and also, the slope units are classified into three different classes i.e. Cataclinal $\left(a_{c}\right)$, Anaclinal $\left(a_{a}\right)$ and Orthoclinal $\left(a_{0}\right)$ using the value of Chord Length (L) of the slope units (table-7).

Only for the relationship between S and $\xi$, the $\mathrm{T}>\mathrm{T}_{0.975(\mathrm{df}=\mathrm{x})}$; so, in this case, the null hypothesis is rejected. For rest of the cases, $\mathrm{T}<\mathrm{T}_{0.975(\mathrm{df}=\mathrm{x})}$; hence, Null Hypothesis is accepted; therefore, these relationships are statistically insignificant. The test of significance bring to fore the conclusion that altitude, direction of topographic slope and magnitude as well as azimuth of bedding dip, as individual factors, hardly influence the issue of hill slope instability. Only, the magnitude of topographic slope shows significant positive relationship with the degree of slope instability in the area under observation. Under this circumstance a combination of topographic and bedding parameters are required to be correlated with the WISI to interpret the morpho-structural influence on hill slope instability.

The Topographic-Bedding Plane Intersection Angle (TOBIA) has been calculated for each of 43 slope units and also, the slope units are classified into three different classes i.e. Cataclinal ( $\mathrm{a}_{\mathrm{c}}$ ), Anaclinal $\left(a_{a}\right)$ and Orthoclinal $\left(a_{0}\right)$ using the value of Chord Length (L) of the slope units.

TOBIA ( $\tau$ ) is placed along X-axis and the Weighted Index of Slope Instability ( $\xi$ ) is placed along Y -axis for different
categories of slopes separately to analyse the association between the two variables.

The scatter diagram of three different kinds of slopes (figure-2) shows very unique response of hill slope instability with the variation of topographic-geologic surface conformity. In each diagrams both the linear and 2 nd order polynomial trend lines (continuous and dashed line) are drawn to observe the general trend of relationship as well as the trend of variation of the relationship within the entire range of observations.

To follow Meentemeyer and Moody ${ }^{14}$ regarding the response function of TOBIA ( $\tau$ ), as an index for representing the statistical relationship between the conformity between topographic and bedding surfaces, it can be stated that the values of $\tau$ for cataclinal slopes range between 0 and 1 ; for dip-slopes where $\Theta$ and $S$ are equivalent, value of $\tau$ increases towards ' 1 '; whereas value of $\tau$ decreases towards ' 0 ' when $\Theta$ and $S$ become unaligned extremely. In the case of anaclinal slopes, $\tau$ decreases if either $\Theta$ or $S$ increases away. For the orthoclinal slopes, the cosine value of the difference of azimuth of bedding dip $(\alpha)$ and topographic slope (A) of the TOBIA equation does adjust the value of $\tau$ by quantifying the degree to which dip direction and slope aspect are aligned. Here, the $\tau$ value ranges from 1 (where, $\Theta$ and $S$ are low) to 0 (where, $\Theta$ and $S$ are high). From figure 1 (a), as the $\tau$ become increasing from ' -1 ' to ' 0 ' to ' 1 ', the value of $\xi$, representing the instability decreases away. Being the anaclinal slope, the azimuth of surface slope and bedding dip are compass opposite; this implies - when both the $\Theta$ and $S$ are low, i.e. $\tau$ shows higher value, the $\xi$ index shows lower value; and when the value of $\Theta$ and $S$ increase away, the slope becomes comparatively instable envisaged by the higher $\tau$ value which results into lowering the $\xi$ value. From figure 1(b), when $\Theta$ and $S$ are nearly equivalent to indicate the tendency of the slope to be dip slope and the $\tau$ reflects higher value in this circumstance, the value of $\xi$ is also higher. It may be described as the tendency of land slips increases in cataclinal dip slopes. Being the $\tau$ value in cataclinal slope ranges between ' 0 ' and ' 1 ', the value of $\tau>$ 0.5 may be casually stated as the situation of geologic surface tending to get equivalent with topographic surface. As the $\tau$ value is getting higher, the hill slope is getting instable as shown by comparatively higher value of $\xi$. From figure $1(\mathrm{c})$, the value of $\tau$ as getting higher, the slope surface is considered to have getting aligned with the bedding; which is accompanied with the lowering tendency of the value of $\xi$ to reflect the observed stability.

## Conclusion

Alignment of rock strata and their style of exposure on the surface of the hill slopes have a significant impact in determining the issues of stability of a particular geomorphic slope unit. This basic relationship is worthy to be examined vividly during the framing of land use plans over the slopes. Presently, the Himalayan Mountain slopes are being modified rapidly due to the augmented quest of developing tourism economy in the hilly tracts. The large scale infrastructural development plans and other heavy construction works may lead to further instability to hill slopes if the locations of such activities are not allocated rationally. Present study is the effort of establishing only one factor responsible for the slope instability in a particular river basin of Garhwal Himalaya; and the findings of the study unfold the scope of the verification and further extension of the particular issue; and, obviously, the inclusion of other factors may explain the situation more effectively. The rational decision making process in terms of hill slope land use and sustainable hill slope modification may be the answer of the dilemma of maintaining a rational balance between the development and the environmental conservation.
